

Newsflow: An R package for analyzing content homogeneity and news diffusion using computational text analysis

by Kasper Welbers and Wouter van Atteveldt

Abstract

Given the sheer amount of news sources in the digital age (e.g., newspapers, blogs, social media) it has become difficult to determine where news is first introduced and how it diffuses across sources. We introduce Newsflow: an R package for analyzing content homogeneity and diffusion patterns using computational text analysis. The content of news messages is compared using techniques from the field of information retrieval, similar to plagiarism detection. By using a sliding window approach to only compare messages within a given time distance, it is made easy to compare many sources over long periods of time. Furthermore, the package introduces an approach for analyzing the news similarity data as a network, and includes various functions to analyze and visualize this network.

Introduction

The news diffusion process in the digital age involves many interdependent sources, ranging from news agencies and traditional newspapers to blogs and people on social media [Meraz, 2011, Paterson, 2005, Pew Research Center, 2010]. We offer the `Newsflow` package¹ as a toolkit to analyze the homogeneity and diffusion of news content using computational text analysis. This analysis consists of two steps. First, techniques from the field of information retrieval are used to measure the similarity of news messages (e.g., addressing the same event, containing identical phrases). Second, the temporal order in which messages are published is used to analyze consistent patterns in who follows whom.

The main contribution of this package lies in the specialized application of document similarity measures for the purpose of analyzing the homogeneity and diffusion of news. News is a special type of information in the sense that it has a time dimension—it quickly loses its relevance. This package uses this by offering a function that calculates the similarity of documents using a sliding window approach, to compare only documents that occur within a given time distance. This makes it computationally feasible to compare many documents across long time periods, thus enabling comparative and longitudinal analysis. In addition, the package offers tools to organize, analyze and visualize the document similarity data.

The primary intended audience of this package is scholars and professionals in fields where the impact of news on society is a prime factor, such as journalism, political communication and public relations [Baum and Groeling, 2008, Boczkowski and De Santos, 2007, Ragas, 2014]. To what extent the content of certain sources is homogeneous or diverse has implications for central theories of media effects, such as agenda-setting and the spiral of silence [Bennett and Iyengar, 2008, Blumler and Kavanagh, 1999]. Identifying patterns in how news travels from the initial source to the eventual audience is important for understanding who the most influential “gatekeepers” are [Shoemaker and Vos, 2009]. Furthermore, the document similarity data enables one to study news values [Galtung and Ruge, 1965] by analyzing what elements of news predict their diffusion rate and patterns.

The package is designed to appeal to scholars and professionals without prior experience in computational text analysis. This paper covers the entire chain from processing raw data—written text with source and date information—to analyzing and visualizing the output. It points to relevant software within and outside of R for preprocessing written texts, and demonstrates how to use the core functions of this package. For more advanced users there are additional functions and parameters to support versatility. `Newsflow` is completely

¹Note to reviewer. The target journal for this manuscript is the R Journal, which specifically focuses on papers that introduce new packages for the R statistical software. As such, convention is that it is not explained what R is. For reference, R is an open-source statistical software package (<https://www.r-project.org/>).

open-source to promote active involvement in developing and evaluating the methodology. The source code is available on Github—<https://github.com/masked> (repository hidden for review).

The first part of this paper discusses the data preparation. There are several choices to be made here that determine on what grounds the content of documents is compared. The second part shows how the core function for calculating document similarities is used. The third part demonstrates functions for exploring, using and visualizing the document similarity data. All the code used for this demonstration is reported, and the demo data is included in the package for easy replication.

Preparing the data

To analyse content homogeneity and news diffusion using content analysis, we need to know *who* said *what* at *what time*. Thus, our data consists of messages in text form, including meta information for the source of the message and the date it was published. The texts first need to be *pre-processed* into formal data. This section refers to existing software—both within and outside of R—to create a DTM, and reflects on how certain pre-processing choices affect the analysis. Furthermore, it shows how the source and date information should be organized.

The texts need to be represented as a document-term matrix (DMT). This is a matrix in which rows represent documents, columns represent terms, and cells indicate how often each term occurred in each document. A DTM is referred to as a *bag of words* representation of texts, since we ignore the order of words. This simplified representation enables common computational analysis, and as research points out that “a simple list of words, which we call unigrams, is often sufficient to convey the general meaning of a text” [Grimmer and Stewart, 2013, 6].

As input for this package, the DTM has to be in the `DocumentTermMatrix` class of the `tm` package, which is a popular package for text mining in R. The `tm` package contains functions to create a DTM based on raw text in various formats. We also recommend the `RTextTools` package, which combines `tm` functions in a single `create_matrix` function. For example, consider the following DTM containing three texts: “Socrates is human”, “Humans are mortal” and “Therefore, Socrates is mortal”.

	are	human	humans	is	mortal	socrates	therefore
Document 1	0	1	0	1	0	1	0
Document 2	1	0	1	0	1	0	0
Document 3	0	0	0	1	1	1	1

Based on the representation of texts in the DTM, the similarity of documents can be calculated as the similarity of row vectors. With this approach, simply looking at all words in their literal form has certain pitfalls. For instance, the words “human” and “humans” are given separate columns. As a result, this similarity of the first two texts is not recognized. Also, the words “are”, and “is” do not have any particular meaning, so they are not informative and can be misleading for the calculation of document similarity. There are various techniques to filter and transform words that can be used to mend these issues. In addition, we can use these techniques to steer on what grounds documents are compared.

- First of all, it is advisable to make all terms lowercase, and reduce terms to their root using stemming or lemmatizing². Thus, “Hope”, “hoped”, “hoping”, etc. all become “hope”. This is because we are interested in the meaning of these terms, and not the specific form in which they are used.
- Second, one should filter out irrelevant words. Very common words, stopwords and boilerplate words contain little or no relevant information about news items. Very rare terms, while ignored in many

²Stemming and lemmatization are both techniques for reducing words to their root, or stem. This is used to group different forms of the same word together. Without going into specifics, the difference is that lemmatization is a much more computationally demanding approach, but generally gives better results. Especially for richly inflected languages such as German or Dutch it is highly advised to use lemmatization instead of stemming.

computational text analysis approaches, are particularly informative for our current purpose, and should be kept.

- Third, It is also possible to specifically select or filter out only certain types of words by using part-of-speech tagging³. For instance, to compare whether documents address the same event one can focus on nouns and proper names.
- Finally, an alternative approach is to combine words into N-grams (i.e. sets of N consecutive words). This way the comparison of documents focuses more on similarity in specific segments of text, which is useful if the goal is to trace whether news outlets literally copy each other (in which case most other pre-processing steps can be skipped).

All mentioned techniques except for lemmatizing and part-of-speech tagging are available in the `tm` package and in the `create_matrix` function of the `RTextTools` package. To use lemmatization or part-of-speech tagging there are several free to use grammar parsers, such as *CoreNLP* for English [Manning et al., 2014] and *Frog* for Dutch [Van den Bosch et al., 2007].

For this paper, data is used that has been preprocessed with the Dutch grammar parser *Frog*. The data is based on a recent study on the influence of a Dutch news agency on the print and online editions of Dutch newspapers in political news coverage (Author citation, forthcoming). The terms have been lemmatized, and only the nouns and proper names of the headline and first five sentences (that generally contain the essential who, what and where of news) are used. By focusing on these elements, the analysis in this study focused on whether documents address the same events. This data is also made available in the package as demo data, in which the actual nouns and proper names have been replaced by numbered types.

```
data(dtm)
as.matrix(dtm[1:3,1:5])
```

	person.688	noun.1516	location.119	organization.323	person.493
35573532	0	0	0	0	0
35573536	0	0	0	0	0
35573539	0	0	0	0	0

In addition to the DTM, we need meta information about (at least) the publication time and source of each document. This should be structured as a data frame that contains a column labeled `document_id`, that should match with the rownames (i.e. documents) of the DTM. The date values should be in the `Date` or `POSIXct` class.

```
data(meta)
head(meta,3)
```

document_id	date	source	sourcetype
35573532	2013-06-01 06:00:00	Newspaper 2 print	Print newspapers
35573536	2013-06-01 06:00:00	Newspaper 2 print	Print newspapers
35573539	2013-06-01 06:00:00	Newspaper 2 print	Print newspapers

Given the DTM and meta information, we can calculate statistics for the occurrence of words, based on which we can filter out words that are not relevant for our analysis. Since we are analyzing news diffusion, a particularly interesting characteristic of words is the distribution of their use over time. To focus the

³Part-of-speech tagging is a technique that identifies types of words, such as verbs, nouns and adjectives.

comparison of documents on words that indicate new events, we can filter out words that are evenly used over time. To calculate this, we offer the `term.day.dist` function.

```
tdd = term.day.dist(dtm, meta)
head(tdd)
```

term	freq	doc.freq	days.n	days.pct	days.entropy	days.entropy.norm
person.688	1	1	1	0.033	1	0.033
noun.1516	4	3	1	0.033	1	0.033
location.119	1	1	1	0.033	1	0.033
organization.323	2	2	1	0.033	1	0.033
person.493	3	2	1	0.033	1	0.033
noun.1415	2	2	1	0.033	1	0.033

The most interesting output is the `days.entropy` score, which is the entropy of the distribution of words over days. This tells us whether the occurrence of a word over time is evenly distributed (high entropy) or concentrated (low entropy).⁴ The maximum value for entropy is the total number of days (in case of a uniform distribution). The `days.entropy.norm` score normalizes the entropy by dividing by the number of days. By selecting the terms with low entropy scores, the DTM can be filtered by using the selected terms as column values.

```
select_terms = tdd$term[tdd$days.entropy.norm <= 0.3]
dtm = dtm[,select_terms]
```

Calculating document similarities

To efficiently compare many documents, a vector space model (VSM) approach is used [Salton et al., 1975, Salton and Harman, 2003].⁵ An established and often used VSM approach is to first weight the document vectors using the tf.idf (term frequency - inverse document frequency) weighting scheme, and then calculate the similarity of the document vectors based on the cosine distance of their angles. Although this package allows other weighting schemes and similarity measures to be used, this paper uses (and currently recommends) the tf.idf and cosine similarity approach.

The `tm` package offers several ways to weight a DTM in the `DocumentTermMatrix` class. To weight on tf.idf, the `weightTfIdf` function can be used.

```
dtm = weightTfIdf(dtm)
```

Given a (weighted) DTM and corresponding document meta data, the document similarities over time can be calculated with the `documents.window.compare` function. This function has two main data inputs: the DTM and a data.frame with meta information. The meta data.frame should have a column containing document id's that match the rownames of the DTM (i.e. documents) and should have a column indicating the publication time. By default these columns should be labeled 'document_id' and 'date', but this can be set using the `id.var` and `date.var` parameters. Any other columns will automatically be included as document meta information in the output.

Furthermore, three parameters are of particular importance. The `hour.window` parameter determines the time window in hours within which each document is compared to other documents. The argument is a vector

⁴Note that this is also a good automatic approach for filtering out stopwords, boilerplate words, and word forms such as articles and common verbs.

⁵In future versions alternative document similarity measures will be added.

of length 2, in which the first and second value determine the left and right side of the window, respectively. For example, `c(-36,0)` will compare each document to all documents within the previous 36 hours. The `measure` parameter, which determines what measure for similarity is used, defaults to *cosine similarity*. This is a commonly used measure, which indicates similarity as a score between 0 (no similarity) and 1 (identical)⁶. The `min.similarity` parameter is used to ignore all documents pairs below a certain similarity score. This reduces the size of the output, which can be necessary with larger datasets, given that the number of document pairs increases exponentially as the number of documents increases.

```
g = documents.window.compare(dtm, meta,
                             hour.window = c(-36,0),
                             min.similarity = 0.4)
```

The output `g` is a network, or graph, in the format of the `igraph` package. The vertices (or nodes) of this network represent documents, and the date and source of each document are stored as vertex attributes. The edges (or ties) represent the similarity of documents, and the similarity score and time difference are stored as edge attributes. An advantage of using a network format is that it combines this data in an efficient way, without copying the vertex meta information for each edge. This network forms the basis for all the analysis function offered in this package⁷. Alternatively, both elements of the data can easily be viewed or extracted with the `get.data.frame` function of the `igraph` package.

```
v = get.data.frame(g, 'vertices')
e = get.data.frame(g, 'edges')

head(v,3)
```

	name	date	source	sourcetype
97360803	97360803	2013-06-03 16:54:00	Newsagency	Newsagencies
35734376	35734376	2013-06-03 18:13:00	Newspaper 1 online	Online newspapers
97361657	97361657	2013-06-05 09:21:00	Newsagency	Newsagencies

```
head(e,3)
```

from	to	weight	hourdiff
35734376	97360803	1	-1.32
36022422	97361657	1	-1.12
36043529	97361740	1	-2.08

The `weight` attribute of the edges represents the similarity score. The `hourdiff` attribute represents the time difference in hours between two documents, where a negative score indicates that the `to` article was published before the `from` article. Note that this corresponds with the `hour.window` parameter of the `documents.window.compare` function. A histogram can provide a good first indication of this data.

```
hist(E(g)$hourdiff, main='Histogram of time distance between documents in hours',
     xlab = 'Lag in hours', breaks = 100)
```

⁶If the DTM contains negative values, the cosine similarity score can range from -1 to 1.

⁷If data about document similarities is imported, then the `document.network` function can be used to create this network. This way the analysis functions of this package can still be used.

Histogram of time distance between documents in hours

In the histogram we see that most document pairs with a similarity score above the threshold are about an hour apart (-1 on the x-axis). This is mainly because the online newspapers often follow the news agency within a very short amount of time. As time distance increases, the number of document pairs decreases, which makes sense because news gets old fast, so news diffusion should occur within a limited time after publication.

If the goal of the document comparison is to analyze news diffusion patterns, then there is one more thing to account for. If news diffuses from one news outlet to another, then the time difference cannot be zero, since the news outlet that follows needs time to edit and publish the news. This delay period can also differ between news outlets. Websites can adopt news within minutes, but newspapers have a long time between pressing and publishing the newspaper, meaning that there is a period of several hours before publication during which influence is not possible. To make it more convenient to tailor (and store) the lag settings for each news outlet, we made the `source.window.settings` and `filter.lag` functions.

The `source.window.settings` function creates a data.frame that contains for each source the minimum and maximum amount of lag. Alternatively, if the meta information also contained another relevant grouping attribute such as source type, this can also be used, as we'll demonstrate.

In the following example the minimum and maximum lag is set to 0.1 and 36 hours, respectively. For print newspapers, the minimum lag is then manually set to 6 hours to account for their publication delay.⁸

```
source.window = source.window.settings(g, max.window.left = -36, max.window.right = -0.1,
                                       meta.attribute='sourcetype')
source.window$window.right[source.window$sourcetype == 'Print newspapers'] = -6
source.window
```

sourcetype	window.left	window.right
Newsagencies	-36	-0.1
Online newspapers	-36	-0.1
Print newspapers	-36	-6.0

The advantage of this approach is that the source window data.frame can now easily be stored for future reference. Next, `filter.lag` uses the data.frame to filter the data in the network. Also, to display the actual range of the window for each source, the `show.source.window` function can be used.

⁸Note that the `source.window.settings` function also has a `direct.edit` parameter, which invokes a text editor to make manual adjustments.

```
g = filter.window(g, source.window)
show.window(g)
```

source	window.left	window.right
Newsagency	-35.4	-0.150
Newspaper 1 online	-35.8	-0.100
Newspaper 1 print	-36.0	-7.017
Newspaper 2 online	-36.0	-0.117
Newspaper 2 print	-35.1	-7.350

Note that currently we are only comparing documents to prior documents. This way, we focus the analysis on whether each document is potentially influenced by certain other documents. By changing the window setting, it is also possible to compare each document to both prior and future documents, to focus on content homogeneity. Or to compare only to future documents, to focus the analysis on whether each document potentially influenced other documents.

Aggregating and visualizing the document similarity network

Before we aggregate the network, it can be informative to look at the individual components. That is, disconnected parts of the network consisting of one or more documents that are only similar to each other. With the current data, these components tend to reflect documents that address the same or related events. To inspect components, we can use the `plot.document.network` function. This function draws a network where nodes (i.e. documents) are positioned based on their date and time (x-axis) and source (y-axis). If an integer is given as an argument for the `subcomp` parameter, then this specific subcomponent is visualized and returned. Without the `subcomp` parameter the entire network will be plotted, which is only useful with smaller graphs. If a DTM is also provided, the visualization will include a word cloud with the common words of these documents. Also, the source attribute can be changed to other interesting meta attributes such as source type.

```
## Visualize and extract individual components of the network
sg2 = plot.document.network(g, subcomp = 2, dtm=dtm)
```

```
sg2_sourcetype = plot.document.network(g, subcomp = 2, source.attribute = 'sourcetype')
```

The first visualization (per source) shows that a news message was first published by the news agency on June 6th, and adopted the same day by two online newspapers, and also that one newspaper later on published an update or follow-up item. Note that the subcomponents are also stored as separate networks `sg1` and `sg2`, so that they can be inspected more specifically.

These visualizations illustrate how we can analyze homogeneity and news diffusion patterns. For each source we can count what proportion of its publications is similar to earlier publications by specific other sources. We can also analyze the average time between publications.

The `aggregate.network` function performs these calculations by aggregating the edges in the network based on the vertex attributes (i.e. the meta information). The first argument is the `igraph` network. The arguments for `by.from` and `by.to` are character vectors to indicate one or more vertex attributes. This gives flexible control over the data, for instance to analyze source to source influence, or source to sourcetype, or to analyze per month (after adding month as a vertex attribute). By default, the function returns the number of edges, as well as the number of nodes that is connected for both the `from` and `to` group. In addition, an `edge.attribute` can be given and a function to aggregate this attribute. For this example we use this to analyze the median of the `hourdiff` attribute.

```
source_to_source = aggregate.network(g, by.from = 'source', by.to='source',
                                     edge.attribute='hourdiff', agg.FUN=median)
s.type_to_s.type = aggregate.network(g, by.from = 'sourcetype', by.to='sourcetype',
                                     edge.attribute='hourdiff', agg.FUN=median)
```

```
## Table printed in two parts due to width
head(s.type_to_s.type[,1:7])
```

from.sourcetype	to.sourcetype	edges	agg.hourdiff	from.matched	from.N	from.prop
Online newspapers	Newsagencies	830	-1.30	714	879	0.812
Newsagencies	Newsagencies	124	-8.08	95	597	0.159
Print newspapers	Newsagencies	98	-16.09	79	278	0.284
Newsagencies	Online newspapers	180	-5.62	114	597	0.191
Online newspapers	Online newspapers	379	-1.83	291	879	0.331
Print newspapers	Online newspapers	155	-15.05	86	278	0.309

```
head(s.type_to_s.type[,c(1:4, 8:10)])
```

from.sourcetype	to.sourcetype	edges	agg.hourdiff	to.matched	to.N	to.prop
Online newspapers	Newsagencies	830	-1.30	543	597	0.910
Newsagencies	Newsagencies	124	-8.08	112	597	0.188
Print newspapers	Newsagencies	98	-16.09	89	597	0.149
Newsagencies	Online newspapers	180	-5.62	158	879	0.180
Online newspapers	Online newspapers	379	-1.83	334	879	0.380
Print newspapers	Online newspapers	155	-15.05	143	879	0.163

The default output is a data.frame where the edges of each unique combination of the **from** and **to** groups are aggregated. For example, we see that online newspaper documents have 830 edges to news agency documents that were published within the previous 36 hours. The median of the difference in hours of these documents is -1.3 (1 hour and 18 minutes). The **from.matched** column indicates the number of unique online newspaper documents that matched with a news agency document⁹. The **from.N** column indicates the total number of online newspaper documents, and **from.prop** is the proportion of online newspaper documents that matched with a news agency document. Substantially, the **from.prop** score thus indicates that 81.23% of political news in online newspapers is similar or identical to recent news agency news. This indicates that online newspapers rely heavily on the news agency as a source of political news.

The **matched**, **N** and **prop** scores are also reported for the **to** group. This gives an interesting inversed perspective on the relation between online newspapers and news agencies. Based on the **to.prop** score, we see that 90.95% of political news published by the news agency is similar or identical to future online newspaper news. If a news agency publishes a political news item, it is very likely that this item will soon after be published by at least one online newspaper. Thus note that **from.prop** and **to.prop** are related but different scores, and can be used complementary or to answer different research questions.

In the current aggregation we looked at all edges, but depending on the purpose of the analysis it can be relevant to filter first. For illustration, look again at the first visualization of the subcomponent. Here the publications of **Newspaper 1** online match previous publications of both the news agency and the other online newspaper. If we are specifically interested in who the original source of the news is, then it makes sense to only count the edges to the news agency. This package therefore offers the **only.first.match** function, which will transform the network so that each document can only have 1 edge: to the earliest dated document it matches within the specified time window.

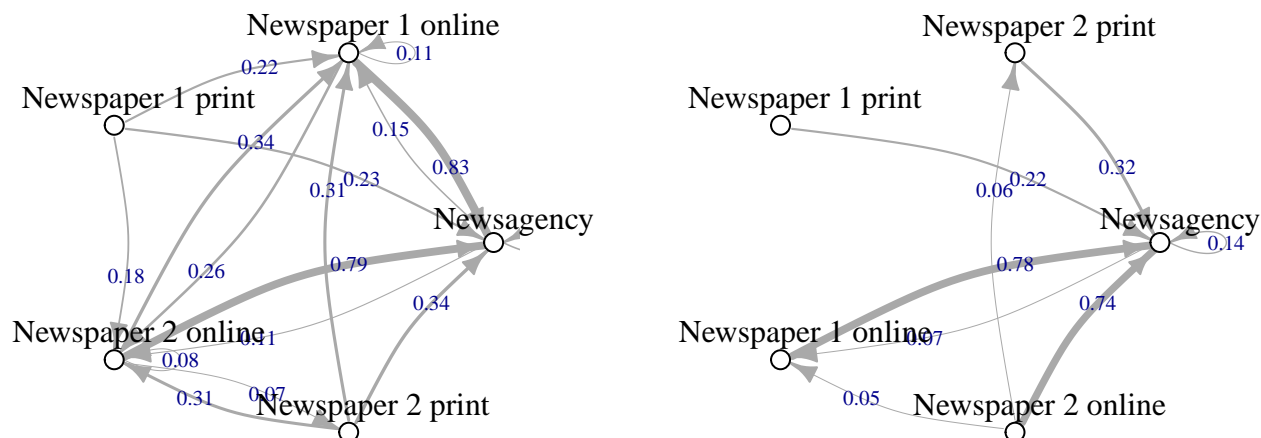

To demonstrate how this affects the results, we compare the previous aggregation with an aggregation of the transformed network. For this, we also demonstrate the **return.network** parameter of the **aggregate.network** function, which returns the output as an **igraph** network. For the edge weight we use the **from.prop** score. We plot both networks, using a threshold of 0.05 for the proportion score for the sake of parsimony.

```
g2 = only.first.match(g)
permed.g1 = aggregate.network(g, by.from='source', by.to='source',
                             return.network = T, network.edge.weight = 'from.prop')
permed.g2 = aggregate.network(g2, by.from='source', by.to='source',
                             return.network = T, network.edge.weight = 'from.prop')

permed.g1 = delete.edges(permed.g1, which(E(permed.g1)$weight < 0.05))
permed.g2 = delete.edges(permed.g2, which(E(permed.g2)$weight < 0.05))

par(mfrow = c(1,2))
plot(permed.g1, layout=layout.circle, vertex.label.dist=0.6, edge.label.cex = 0.7)
plot(permed.g2, layout=layout.circle, vertex.label.dist=0.6, edge.label.cex = 0.7)
```

⁹Note that the **edges** score can be higher (but not lower) than the **from.matched** score, since one document can match with multiple other documents.

The first network is much more dense compared to the second. In particular, we see stronger edges between the print and online editions of the newspapers. In the second network almost only the ties to the news agency remain. This implies that many of the edges between newspapers result from cases where both newspapers adopt the same news agency articles.

Note that the second network is not better per se. Consider, for instance, that a blog might most of its information from an online newspaper, in which case the news agency is often still the initial source, but the newspaper is a crucial gatekeeper. Depending on the purpose of the analysis, either approach can thus be more suitable.

Finally, a useful alternative way to organize the data is as a data.frame that shows for each document whether and if so how strongly it matches with other sources. For this we can use the `topSimilarities` function. The output is a data.frame where the rows represent unique documents. For each document the score for the strongest match to each other source is given (or zero if no match is found). In this format the data can easily be matched to data on content characteristics of individual documents.

```
topsim = topSimilarities(g, break.by='sourcetype')
head(topsim,4)
```

id	date	Newsagencies	Print newspapers	Online newspapers

Conclusion and future improvements

We have demonstrated how the *newsflow* package can be used to perform a many-to-many comparison of documents. The primary focus and most important feature of this package is the `documents.window.compare` function. This function compares all documents that occur within a given time distance, which makes it computationally feasible for longitudinal data. Using this data, we can analyze to what extent different sources publish the same content and whether there are consistent patterns in who follows whom. The secondary focus of this package is to provide functions to conduct this analysis, and to provide a platform for scholars to share additional or alternative approaches.

The data input required for this analysis consists solely of textual documents and their corresponding publication date and source. If the texts are imported as natural language, the `tm` package or `RTextTools` package can be used to preprocess them and to create a DTM. If the texts are imported as preprocessed tokens, the `create.dtm` function can be used to create a DTM. Since no human coding is required, the

package enables large scale comparative and longitudinal studies. Although the demonstration in this paper used a moderate sized dataset, the functions can handle much larger data ¹⁰.

The goal is to continue developing this package as a specialized toolkit for analyzing the homogeneity and diffusion of news content. First of all, additional approaches for measuring whether documents are related will be added. Currently only a vector space model approach for calculating document similarity is implemented¹¹. For future versions alternative approaches such as language modeling will also be explored. In particular, we want to add alternative measures to express the relation of documents over time in terms of probability and information gain. This would also allow us to define a more formal way to determine whether or not a relation exists, other than using a similarity threshold. Secondly, new methods for analyzing and visualizing the network data will be explored. In particular, methods will be implemented for analyzing patterns beyond dyadic ties between news outlets, building on techniques from the field of network analysis.

Ultimately, the goal is to extract communication networks from content data for many sources over time. This package contributes to this goal by facilitating different approaches for creating and aggregating the document network.

¹⁰A test showed that on a laptop with 8Gb RAM and a 1.80GHz processor (no multi-threading used) the analysis performed well with a DTM containing 315.000 documents and 120.000 unique terms. This data covered 1 year in 14 sources, and a window of 3 days and threshold of 0.4 was used.

¹¹This is because we currently rely on matrix multiplication as a computationally efficient way to calculate inner-product based similarity scores, such as cosine similarity.
